

## CHAPTER 3

# Data Analysis

The first section of this chapter presents the methodological approach and related issues. The second section presents the data used in the development of the prediction models and AMFs.

### Methodology

Over the past decades, interest has increased in estimating the safety implications from changes in various design elements. To be able to determine these changes, models were developed that could predict the crash-rate frequency or the number of crashes as a function of various traffic conditions and values of geometric elements. A significant part of past research was devoted to developing such models; in the past decade, most researchers have used negative binomial models for modeling crashes. These models assume that unobserved crash variation across roadway segments is gamma-distributed, while crashes within sites are Poisson-distributed (41). The Poisson, Poisson-Gamma (negative binomial), and other related models are collectively called "generalized linear models" (GLM). These models have the general form of Equation 1:

$$E[N] = EXPO \cdot e^{b_0 + b_1 X_1 + b_2 X_2 + \dots + b_n X_n} \quad (1)$$

where

$E[N]$  = predicted number of crashes per year for a roadway section,

$EXPO$  = exposure to crashes,

$b_0, \dots, b_n$  = regression coefficients, and

$X_1, \dots, X_n$  = predictor variables.

Models developed similar to Equation 1 will be capable of identifying the relationship of the number of crashes to the various elements to be considered. The measure of exposure used in these prediction models could be either the traditional vehicle-miles (i.e., length  $\times$  Average Daily Traffic (ADT) volume), or the length itself while the ADT becomes a predictor variable.

Negative binomial models are typically used in developing Crash Reduction Factors (CRFs) or Accident Modification Factors (AMFs). Even though these two terms are in general similar in concept, there are slight differences. A CRF is a value that represents the reduction of crashes due to a safety improvement at a roadway spot or section. Such values represent the percent improvement on the roadway and most often have a positive connotation—that is, the safety intervention will have a positive result. On the other hand, an AMF is a constant that represents the safety change due to a change in a value of the segment. These factors are typically the ratio of the expected values of crashes with and without the change. AMFs are also used as multipliers for estimating the expected number of crashes, and values less than 1.0 indicate fewer crashes as a result of the change.

The basic concept of the AMF is to capture the change in crash frequency due to the change of a single element. However, this is often not the case, and these factors have been developed using cross-sectional studies where multivariate models were developed and used in the determination of AMFs. The models typically include all contributing factors that could influence safety and then use them to estimate the change in crashes due to a change in one unit of the variable of concern. This approach is typically completed with the assistance of an expert panel that evaluates the use of the prediction models and estimates the potential effect for each variable of concern. These evaluations could be further supported by the existing literature and current knowledge for the specific variable. This approach was used in the two-lane rural roadway models as part of the IHSDM, where the models developed were used as the basis for the creation of the AMFs. AMFs may appear subjective in nature, but they represent a collective "wisdom" based on expert panel knowledge, field observation, and findings in the research literature. The key limitation to this approach for AMF development is that there may not be adequate literature dealing with the identification of the safety impacts from the elements of interest.
